Researchers sought to examine whether there are patterns of oral hypoglycemic-agent adherence among primary-care patients with type 2 diabetes that are related to patient characteristics and clinical outcomes. Longitudinal analysis via growth curve mixture modeling was carried out to classify 180 patients who participated in an adherence intervention according to patterns of adherence to oral hypoglycemic agents across 12 weeks. Three patterns of change in adherence were identified: adherent, increasing adherence, and nonadherent. Global cognition and intervention condition were associated with pattern of change in adherence ($p < .05$). Patients with an increasing adherence pattern were more likely to have a Hemoglobin A1c ($\text{HbA1c} < 7\%$; adjusted odds ratio = 14.52, 95% CI (2.54, 82.99) at 12 weeks, in comparison with patients with the nonadherent pattern. Identification of patients with type 2 diabetes at risk of nonadherence is important for clinical prognosis and the development and delivery of interventions.

Keywords: adherence, diabetes mellitus, glycemic control, primary health care, randomized controlled trials

Achieving optimal glycemic control is a cornerstone in reducing risk for microvascular and macrovascular complications in type 2 diabetes.$^1$ Despite the development of effective diabetes therapies and interventions to prevent both macrovascular and microvascular complications and adverse events, diabetes control remains suboptimal.$^2-^5$ Oral hypoglycemic adherence is a critical component of diabetes treatment regimens with guideline concordant adherence being associated with improved glycemic control, lower disease-related health-care expenditures, and...
reduced mortality.6,7 However, adherence estimates generally range between 36% and 93% of prescribed medication regimens for adherence to oral hypoglycemic agents, with a significant proportion of patients failing to meet recommended adherence targets.8,9

Cramer10 and others9–11 reviewed factors associated with adherence to diabetes medicines. Identified factors associated with adherence include age, ethnicity, depression, regimen complexity, dosing frequency of medications, adverse effects, medication costs, patient education and beliefs, and social support. However, these reviews have not specifically considered the issue of oral hypoglycemic agent adherence in primary care and have not examined factors associated with adherence in the context of an intervention. Education alone is insufficient to produce significant adherence behavior change.12 Interventions tailored to the individual focusing on multiple factors inhibiting adherence have been found to be more effective than interventions that are not individually-focused or focus on a single adherence barrier.13,14 Understanding which type 2 diabetes patients are at greatest risk for nonadherence and subsequently poor clinical outcomes based on clinically identifiable patient characteristics would help to identify patients who might benefit from interventions in real world clinical settings.

Investigations attempting to examine individuals at risk for poor adherence share one major shortcoming, they treat adherence as a discrete outcome despite the varying nature of adherence over time. Adherence to oral hypoglycemic agents has been assessed through proportions at singular point(s) in time with little evaluation of variation over time and group classification. We used an innovative technique for longitudinal data analysis, the general growth curve mixture model (GGCMM), in order to study individual differences in adherence and change over time. This technique identifies different subgroups of patients based on their underlying trends and allows for the examination of membership in the subgroups in relation to baseline patient characteristics and subsequent clinical outcomes. Prior work examining adherence to oral hypoglycemic agents has also been limited by recruitment from insurance entities, subjective adherence assessments, and/or primarily Caucasian samples (eg,15–18). We used an objective assessment of adherence, electronic monitoring data, and our sample is drawn from primary care practices serving socioeconomically and ethnically diverse patients.

Our investigation used longitudinal adherence patterns to identify subgroups of type 2 diabetes patients at risk for nonadherence and poor glycemic control at 12 weeks. Our purpose was to further understand (1) the course of oral hypoglycemic agent adherence patterns over 12 weeks among type 2 diabetes patients in primary care, (2) whether such patterns are related to patient characteristics; and, (3) whether patterns predict glycemic control at 12 weeks (Figure 1). We employed data from a primary care randomized controlled trial in which the study intervention was implemented at the patient level and involved an integrated care specialist working with physicians to provide care.19 We hypothesized that type 2 diabetes patients would have distinct patterns of adherence over the 12 week period. We hypothesized based on the literature that patients who were younger, male, non-white, depressed, on a dosing frequency greater than 1 per day, or had a greater medical burden would be more likely than others to have a pattern of nonadherence.15,20–23 In addition, we hypothesized that patients in usual care would be less likely to adhere than patients in the intervention condition. Finally, we hypothesized that patients who were adherent or had increasing adherence across 12 weeks would be more likely to have Hemoglobin A1c (HbA1c), in comparison with patients who were nonadherent. Identifying patterns of adherence to oral hypoglycemic agents over 12 weeks linked to the outcome of glycemic control at 12 weeks will set the stage for interventions targeting resources for persons most at risk for nonadherence.

To our knowledge, no study has examined patient characteristics, pattern of time-varying adherence, and outcome in a primary care trial of diabetes management among type 2 diabetes with the ultimate goal of translating the knowledge into improving clinical outcomes. The Global Burden of Disease Study 2010 and the World Health Organization (WHO) list diabetes as a leading cause of disability.24 According to the WHO, the effectiveness of adherence interventions may have a far greater impact on the health of the population than any improvement in specific medical treatments.25 Identifying type 2 diabetes patients at risk for poor adherence is key to identifying groups of patients at greatest need for intervention and follow-up.

METHODS

Recruitment

A Brief Intervention to Improve Adherence through Integrated Management of type 2 Diabetes Mellitus and Depression Treatment was a randomized controlled trial designed to assess whether an intervention in primary care improved glycemic control and depressive symptoms in type 2 diabetes patients. Patients were recruited from three primary care practices in Philadelphia, Pennsylvania. Patients were randomly assigned to the integrated care intervention or usual care. Electronic medical records were screened between April 2010 to April 2011 for patients with a diagnosis of type 2 diabetes and a prescription for an oral hypoglycemic agent within the past year. The study is described in detail elsewhere.\textsuperscript{19}

Study Design

The purpose of the 2-week run-in phase was to assess the feasibility of use of Medication Event Monitoring System (MEMS) caps and to allow for the collection of pre-intervention adherence rates. Data collected during this phase also included baseline demographics and glycated hemoglobin (HbA\textsubscript{1c}) assays to measure glycemic control. After the two-week run-in phase, phase 2 of the study began in which patients were randomized to the integrated care intervention or usual care.

Intervention and Usual Care

The integrated-care manager worked individually with patients to address factors resulting in nonadherence including depression, chronic medical conditions, function, cognition, social support, cost of medications, side effects, and past experiences with medications. Through in-person sessions and telephone conversations, the integrated-care manager provided education about depression and type 2 diabetes, emphasizing the importance of controlling depression to manage diabetes; help to identify target symptoms; explanations for the rationale for antidepressant and oral hypoglycemic agent use; assessment for side-effects and assistance in their management; assessment for progress (eg, reduction in depressive symptoms, and improvement in finger stick results); assistance with referrals; and monitoring and response to life-threatening symptoms (eg, chest pain, suicidal thoughts and actions).

The intervention was presented to patients as a supplement to, rather than a replacement for, existing primary-care treatment. Over a three-month period, patients had three 30-minute in-person sessions (baseline, 6 weeks, and 12 weeks) and two 15-minute telephone-monitoring contacts. Usual-care patients underwent in-person assessments at the same time points as the intervention. Research assistants conducted all assessments blinded to patients’ randomization status.

Adherence to Oral Hypoglycemic Agents

Adherence to oral hypoglycemic agents was measured using electronic monitoring data obtained from the Medication Event Monitoring System (MEMS) Caps. MEMS caps on pill bottles record the precise date and time of container opening. Electronic drug monitoring data were assessed as the proportion of medication MEMS cap openings in a given week relative to the prescribed doses for the week. Our adherence calculation did not include excessive bottle openings or openings that exceeded the number of prescribed doses for the week.

Glycemic Control

In accordance with American Diabetes Association Guidelines,\textsuperscript{1} blood glycemic control was assessed at baseline and 12 weeks. The in2it A1C Analyzer provides point of care testing and was used to obtain Hemoglobin A\textsubscript{1c} (HbA\textsubscript{1c}) assays. This device has acceptable precision and agreement in comparison with laboratory services.\textsuperscript{26}

Baseline Covariates

Standard questions were employed to obtain patient information on age, gender, ethnicity, marital status, and education. Consistent with prior investigations age was dichotomized as $\geq 60$ years and less than 60 years.\textsuperscript{27} Medical comorbidity was assessed by self-report at baseline. The Mini-Mental State Examination (MMSE) assessed cognitive status and has been widely employed for clinical and research purposes.\textsuperscript{28} The MMSE is a short standardized instrument that assesses orientation to time and place, registration, memory, attention and concentration, praxis, and constructional and language capacity.\textsuperscript{29} As in prior work, MMSE scores were analyzed as a dichotomous variable with a clinical threshold of 27.\textsuperscript{30,31} Functional status was measured using the Medical Outcomes Study Short Form (SF-36).\textsuperscript{32} Depressive symptoms were assessed using the nine-item Patient Health Questionnaire (PHQ-9). The PHQ-9 is a self-administered version of the PRIME-MD diagnostic instrument for mental disorders.\textsuperscript{33}

Analytic Strategy

In the first phase of this analysis, general growth curve mixture models (GGCMs) were applied to indicators of adherence to oral hypoglycemic medication over the 12-week period to identify different adherence patterns.\textsuperscript{34} Binary indicators were adherence measurements assessed by MEMS caps at weekly intervals over a 12-week period. For
We set measures are compared. The model for the adherence cut-point has been used as a standard to which other greater or equal to 80% adherence was used because the 80% cut-point has been used as a standard to which other measures are compared. The model for the adherence patterns included random intercepts and slopes to account for within-subject correlations and separate fixed effect intercepts and fixed effects slopes for time within each latent class or pattern of adherence. We compared the results of this longitudinal linear model to models that accommodated nonlinear changes in adherence across time. The classifications into different patterns of adherence were similar across the different models, so we based our results on the simpler linear model. Number of classes was determined through examination of fit indices (AIC and BIC) as well as for clinically interpretable results. The Rubin-Lo-Mendell test was employed to determine if additional classes added further information to the model.

In the second phase of this analysis, we examined differences in baseline patient characteristics across adherence profile types: adherent ($n = 67$), increasing adherence ($n = 52$), and nonadherence ($n = 61$), using $\chi^2$ for binary variables and analysis of variance (ANOVA) for continuous variables. We added patient characteristics and practice indicators to the GGCMM, one at a time to evaluate their association with class membership. Covariates that were significant at the $p < .10$ level were included in the final model. Next, the relationship between the baseline covariates significant at the $p < .10$ level and latent classes or patterns of adherence was simultaneously assessed. The results were reported as odds ratios and corresponding confidence intervals. The baseline covariates were selected on the basis of previous literature on patient characteristics associated with adherence to oral hypoglycemic agents. We also examined interaction terms for which we had an *a priori hypothesis*: intervention by cognition and an intervention by education.

In the third phase, patients were classified into categories of longitudinal adherence profile types based on the largest posterior probability of membership in a certain class. Logistic regression related latent class variables to the clinical outcome of glycemic control at 12 weeks. Glycemic control was examined both continuously and categorically. As recommended by clinical guidelines, the categorical outcome was assessed using a cutoff of HbA1c $< 7\%$ at 12 weeks. The results of the categorical outcome are presented in the form of odds ratios and 95% confidence intervals. Consistent with prior work, the model included terms to adjust for age, ethnicity, gender, marital status, educational attainment, functional status, frequency of medication administration, number of medications, number of medical conditions, cognitive status, intervention condition, pre-intervention adherence and baseline clinical outcome. We set $\alpha$ at 0.05, recognizing that tests of statistical significance are approximations that serve as aids to inference. The GGCMM was fitted using Mplus Version 7 and other analyses were conducted in STATA version 12 for Windows (STATA Corporation, College Station, TX).

**RESULTS**

**Study Sample**

The CONSORT flow diagram for the Brief Intervention to Improve Adherence through Integrated Management of type 2 Diabetes Mellitus and Depression Treatment trial has been published elsewhere. The protocol was approved by the University of Pennsylvania Institutional Review Board. In brief, out of 715 patients identified by electronic medical records with type 2 diabetes, 265 were eligible and were approached for screening. Among type 2 diabetes patients who were approached, 190 were enrolled (71.7% participation rate). Patients who participated and patients who refused were similar in terms of key demographic characteristics such as age, sex, and ethnicity. After consent was obtained patients were assessed over a 2-week run-in phase in which medication adherence was examined. At the two-week visit, six patients had their medication discontinued, two patients were lost to follow-up and 182 patients were randomized to the integrated care intervention or usual care. In addition, two patients in the integrated care intervention were lost to follow-up subsequent to randomization. The remaining 180 patients completed all study visits.

The mean age of our sample was 57.4 years (standard deviation (SD) 9.5 years, range 32 to 84 years), and 122 (67.8%) of the patients were women. The self-identified ethnicity of patients was 65 white (36.1%), 102 African American (56.7%), 7 Hispanic (3.9%), and 6 (3.3%) who self-identified as “other”. In all, 69 persons (38.33%) were married, and 29 persons (16.1%) had less than a high school education. The mean MMSE score was 28.2 (SD 2.3). Baseline patient characteristics across adherence profile types are displayed in Table 1 (adherent, $n = 67$; increasing adherence, $n = 52$; and nonadherence, $n = 61$). White respondents and patients assigned to the intervention condition were more likely to show an adherent or increasing adherence pattern ($p < .05$). Physical functioning SF-36 score and mini-mental state examination (MMSE) scores significantly differed by adherence profile type ($p < .05$).

**Patterns of Adherence**

Corresponding to the first phase of the analysis, we examined patterns of oral hypoglycemic agent adherence over 12 weeks. In order to delineate these patterns a series of GGCMMs were fitted to the MEMS data. The three-pattern model presented in Figure 2 improved the model fit over...
The Rubin-Lo-Mendell test indicated that the three-pattern model of longitudinal adherence trajectories improved the model fit over the two-pattern model \((p < .001)\), with the four-pattern model providing no additional improvement in fit \((p > .99)\). Entropy, a measure of classification uncertainty, was 96.7% indicating a clear delineation of classes.

Figure 2 shows the patterns of adherence represented by the categorical indicators of adherence at weekly intervals over the 12-week interval. The number of persons assigned to each pattern is presented at the bottom of Figure 2. Patients were assigned to each pattern according to their maximal posterior probabilities in each pattern. The first pattern \((n = 67, 37.0\%\) of the entire sample, “adherent”) represents patients with a high probability of adherence at each time point. Patients with an “adherent” pattern had a probability of adherence at baseline of 72.1% and strongly increasing adherence over time; model slope: 1.54, 95% confidence interval (CI): 0.90, 2.17, with adherence reaching near 100% by the 5th week.

The second pattern represents patients who have a low level of adherence at baseline and improve (“increasing adherence”; \(n = 52, 29.2\%\) of the sample). Patients with “increasing adherence” had a modeled probability of adherence of 30.3% at baseline with a statistically significant increase in adherence over time; model slope of .22 (95% CI: 0.12, 0.32). Modeled adherence reached over 80% by the end of the 12 week period. The third pattern \((n = 61, 33.8\%\) of the entire sample, “nonadherent”) represents patients with a near zero probability of adherence at each time point. Patients with the nonadherent pattern had a near zero probability of adherence at baseline which remained near zero. To provide a more stable model, the slope parameters were fixed at zero for the third pattern of “nonadherent.”

![Figure 2](image-url)
Baseline Type 2 DM Patient Characteristics and Patterns of Adherence

Corresponding to the second phase of our analysis, we examined whether patient characteristics were associated with patterns of adherence to oral hypoglycemic agents. Odds ratios were employed to estimate the association of baseline patient characteristics with patterns of adherence. Two comparisons of patterns of adherence were examined: adherent vs. nonadherent and increasing adherence vs. nonadherent. Patients with MMSE score greater than or equal to 27 were more likely to have an adherent pattern compared to a nonadherent pattern; odds ratio (OR) = 1.29, 95% CI (1.06, 1.57). Patients in the intervention condition were more likely to have an adherent pattern compared to a nonadherent pattern; OR = 11.6, 95% CI (4.08, 32.9). In addition, patients in the intervention condition were more likely to have an increasing adherence pattern compared to a nonadherent pattern; OR = 41.31, 95% CI (13.87, 123.03). In our final model, no associations between age, gender, ethnicity, education, depression status, dosing frequency, number of medications, functional status, or medical comorbidity and classes of adherence were found. We considered potential interaction terms: intervention by cognition and intervention by education, but none reached the level of significance of p < .05.

Clinical Outcome of Patterns of Adherence: Hemoglobin A1c (HbA1c) at 12 Weeks

Corresponding to the third phase of our analysis, we examined whether longitudinal profiles of adherence were associated with glycemic control as assessed by Hemoglobin A1c (HbA1c) at 12 weeks (Table 2). HbA1c at 12 weeks was strongly related to adherence patterns, $\chi^2(2) = 12.82$, $p < .01$. Patients with an increasing adherence pattern were significantly more likely to have an HbA1c < 7%; unadjusted OR = 4.39, 95% CI (1.91, 10.12); adjusted OR = 14.52, 95% CI (2.54, 82.99) at 12 weeks, in comparison with patients with the nonadherent pattern. Patients with an adherent pattern were not significantly more likely to have an HbA1c < 7%; unadjusted OR = 1.86, 95% CI (0.92, 3.76); adjusted OR = 2.24, 95% CI (0.51, 9.92) at 12 weeks, in comparison with the nonadherent pattern. The model included terms to adjust for baseline differences in age, ethnicity, gender, marital status, educational attainment, functional status, frequency of medication administration, number of medications, number of medical conditions, cognitive status, primary care practice, baseline HbA1c, pre-intervention adherence and intervention condition.

DISCUSSION

Examination of adherence over 12 weeks revealed three patterns: adherent, increasing adherence, and nonadherent. Patients who had a MMSE score greater than or equal to 27 were more likely to have an adherent pattern than the nonadherent pattern compared to patients with a MMSE less than 27. Patients in the intervention condition were more likely to have an adherent pattern than a nonadherent pattern, in comparison with patients in usual care. Similarly, patients in the intervention condition were more likely to have an increasing adherence pattern than a nonadherent pattern, in comparison with patients in usual care. Patients with an increasing adherence pattern were also more likely to have an HbA1c < 7% at 12 weeks, in comparison with patients with the nonadherent pattern. Our use of general growth curve mixture models allows us to assess distinct patterns of adherence over time instead of assessing adherence through proportions at singular point(s) in time with no assessment of variation over time. Our finding that patterns of adherence were differentially related to covariates of interest demonstrates the significance of delineating patterns of adherence over time.

Before discussing our findings, the results must first be considered in the context of some potential study limitations. First, we obtained our results from three primary care sites whose patients may not be representative of other primary care practices. However, the three practices were probably similar to other primary care practices in the region as they were diverse and varied in size. Second, there are limitations for all methods for assessing

adherence. MEMS caps were our primary measure of adherence because as an objective measure of adherence they have a low failure rate and are more sensitive than other adherence measures. Any influence of MEMS caps on medication adherence would be experienced equally in both the intervention and usual-care groups. Third, while research has assessed the 80% threshold for some medications, the clinical significance of this threshold has not been tested for many medications. Fourth, the length of follow-up for this trial was 12 weeks. However, significant intent-to-treat effects have been found in diabetes studies for a 12 week time period. Finally, even with confidence in our assessments of exposure, misspecification of the model relating adherence and blood glycemic control is still a possibility, such as when important variables have not been included in our model. We have tried to take care in adjusting our estimates of association for potentially influential characteristics that may relate to the outcome.

Despite these limitations, our results deserve attention because we attempted to characterize patterns of adherence over 12 weeks and the association of patient characteristics, intervention condition, and glycemic control with patterns of adherence. Assessment of a single point in time is insufficient to understand variations in adherence over time. The three patterns of adherence we observed suggest a possible need for more intensive interventions targeting individuals, particularly those with MMSE less than 27. Our results suggest that the intervention condition increased the number of patients with an increasing adherence pattern that might have otherwise have had a nonadherent pattern.

Our results were not wholly consistent with our initial hypotheses. We did not find an association of age, sex, ethnicity, dosing frequency, or medical burden with patterns of adherence. The lack of significant associations of age, sex, ethnicity, dosing frequency, depression status, or medical burden in patients suggests that the effects of these variables did not appear to influence patterns of adherence. In terms of depression status, the onset and nature of clinical diagnosis of depression as well the influence of these diagnoses on functioning may be more important in adherence than symptom presentation. In the examination of medical burden more careful assessment of the type of medical conditions and everyday related tasks that include medication-taking related items may be necessary to find a clear association with medical comorbidity. Given a lack of identification of clear risk profiles for nonadherence, physicians may only be able to suspect nonadherence during the course of treatment for diabetes. If nonadherence is suspected, reasons for nonadherence should be examined and addressed to mitigate poor health prognoses and adverse clinical outcomes.

Patients with MMSE greater than or equal to 27 were more likely to have an adherent than a nonadherent pattern. Past work has demonstrated that individuals with type 2 diabetes show accelerated cognitive decline, particularly in information-processing speed and executive function, compared with individuals without diabetes. While the association between cognition and diabetes is supported by a number of biologically plausible mechanisms, successful diabetes management is largely determined by self-care behaviors such as adherence. Lower cognitive functioning is associated with reduced health literacy and understanding of diabetes management, and greater dependency in persons with diabetes. Furthermore, lower cognitive functioning is also linked to increased risk of poor glycemic control, severe hypoglycemia, and mortality in patients with type 2 diabetes. Patients with lower cognition scores on the MMSE are at risk for a pattern of nonadherence and may need special attention for adherence management.

Our results suggest that the intervention increased the number of patients with an adherent and increasing adherence pattern that might have otherwise have had a nonadherent pattern. The strong association between intervention assignment and adherence pattern substantiates evidence that intervention strategies targeting multiple adherence barriers and which are tailored to the needs of each patient are successful in improving adherence. The interventionist worked individually with patients to address the factors involved in adherence that related to their specific characteristics and medical comorbidity. The high recruitment rates and retention of minorities in this intervention has particular significance given the disproportionate burden of diabetes among minority groups. This is aligned with prior work demonstrating that integrated interventions are more engaging and acceptable to minorities than other intervention approaches. Furthermore, this intervention was both brief and simple in comparison with other diabetes interventions suggesting it may be a sustainable strategy for improving patient adherence that can be implemented in primary care or other settings.

Our findings hold particular clinical significance by demonstrating an increased likelihood of patients with HbA1c < 7% at 12 weeks among patients with an increasing adherence pattern. However, we did not find an association with the adherent pattern and glycemic control. As more is discovered regarding factors influencing adherence over time, we may be able to more accurately identify predictors of glycemic control. The lack of a significant association between the adherent pattern and glycemic control may be indicative of the severity of underlying disease or dosing inadequacy of oral hypoglycemic agents. Patients who are adherent to an inadequate dosage of oral hypoglycemic agents would be less likely to have glycemic control. In the future, longitudinal models may be used to link patient characteristics and patterns of adherence to the likelihood of adequate glycemic control in order to guide clinical treatment. Interventions tailored to the cognitive functioning of patients might have a substantial public health impact on glycemic control. A simple and brief adherence
intervention was strongly related to adherence patterns and clinical outcome. Our results highlight the need for the development, implementation, and dissemination of clinical interventions to enhance medication adherence.

FUNDING

This study was supported in part by two grants from the National Institute of Mental Health: R21 MH094940 and R34 MH085880. Dr. Small was supported by grant SES-1260782 from the Measurement, Methodology and Statistics Program of the U.S. National Science Foundation.
